Meropenem serum concentrations in intensive care patients: a retrospective analysis

Sérové koncentrace meropenemu u pacientů vyžadujících intenzivní péči: retrospektivní analýza

Received November 6, 2020 / Accepted December 2, 2020

Summary

Objectives: To determine whether currently used meropenem dosages in our hospital provide adequate serum concentrations.

Methods: Trough blood samples taken during the first meropenem concentration monitoring were included. For the evaluation of achievement of the pharmacokinetic/pharmacodynamic (PK/PD) target, MIC of the pathogens defined by the European Committee on Antimicrobial Susceptibility testing was selected.

Results: Eighty three patients were enrolled. A large variability in meropenem trough serum concentrations was observed (median 34.3 mg/L, range < 1.0–146.1 mg/L). The lowest PK/PD target for susceptible pathogens (100% $T > MIC$) was achieved in 100% of patients on dialysis and continuous renal replacement therapy (CRRT) and in 91% non-RRT patients. For pathogens with intermediate susceptibility, 100% $T > MIC$ was attained in all patients on CRRT and 96% on dialysis, only 74% non-RRT patients achieved this PK/PD target. Patients on RRT were more likely to achieve the highest PK/PD target 100% $T > 5 \times MIC$, $P < 0.05$. Higher proportion of patients on RRT would also require meropenem dose reduction if upper limit 100% $T > 10 \times MIC$ was chosen, $P < 0.05$.

Conclusions: Administration of a standard meropenem dose to critically ill patients leads to a large concentration variability. Thus, a personalised dosing regimen is crucial for the achievement of adequate meropenem exposure.

Key words: meropenem • trough concentrations • MIC • pharmacokinetic/pharmacodynamic target

Souhrn

Úvod: Cílem retrospektivní analýzy bylo posoudit, zda stávající dávkovací režimy meropenemu vedou k adekvátní expozici meropenemu.

Metody: Do práce byly zahrnuty pouze údolní koncentrace při prvním měření. Ke zhodnocení dosažení farmakokineticko/farmakodynamického (PK/PD) cíle byly použity MIC patogenů definovaných v European Committee on Antimicrobial Susceptibility testing.

Výsledky: Do studie bylo zahrnuto 83 pacientů. Byla pozorována velká variabilita sérových hladin meropenemu (medián 34,3 mg/l, rozptyl < 1,0–146,1 mg/l). Nejnižší PK/PD cíl pro citlivé patogeny (100 % $T > MIC$) byl dosažen u 100 % pacientů na dialýze a kontinuální eliminační metodě (CRRT) a u 91 % pacientů bez eliminační metody. Pro patogeny s intermediární citlivostí 100 % $T > MIC$ bylo dosaženo u všech pacientů na CRRT a 96 % pacientů na dialýze, jen 74 % pacientů bez eliminační metody dosáhlo tento PK/PD cíl. Pacienti na RRT měli vyšší pravděpodobnost dosažení nejvyššího PK/PD cíle 100 % $T > 5 \times MIC$, $P < 0,05$. Vyšší podíl pacientů na RRT by vyžadoval snížení dávky meropenemu, pokud by byl zvolen horní limit 100 % $T > 10 \times MIC$, $P < 0,05$.

Závěr: Aplikace standardní dávky meropenemu kriticky nemocným pacientům vede k velké variabilitě hladin. Nastavení dávky pro konkrétního pacienta je důležité pro dosažení adekvátní expozice meropenemu.

Klíčová slova: meropenem • údolní koncentrace • MIC • farmakokineticko/farmakodynamický cíl

Introduction

Infection and sepsis are major causes of morbidity and mortality in intensive care patients^{1,2}. Treatment of critically ill patients with sepsis and septic shock is complex. Early and adequate antibiotic (ATB) therapy is crucial and associated with favourable clinical outcome. The mainstay of successful antibiotic therapy is selection of a right antibiotic and its application in a sufficient dose so

that adequate concentration at the site of infection can be reached. Improper dosing of ATB has a negative impact on the patient's clinical outcome and increases the risk of developing resistance^{3,4}. A critically ill patient differs in his characteristics from other patients. A rapidly dynamic physiology can cause unpredictable pharmacokinetic alterations that effect antibiotic exposure. Thus antibiotic dosing in critically ill patients might be a challenging and complicated process^{5,6}. Summary of Product Characteristics (SPC), the basis of dosage regimen information for health professionals, is unfortunately based on studies in non-critically ill patients. The pharmacokinetic parameters reported in these patients may differ from those in critically ill patients, so dosing regimens may not be equally applicable and may result in inadequate dosing⁵.

Intravenously administered broad-spectrum β -lactam antibiotics belong among the most frequently prescribed antimicrobials in critically ill patients⁷. When using β -lactam antibiotics in critically ill patients, clinical evaluations suggest maintaining at least 100% $fT > MIC$ may be necessary (100% of time of free antibiotic concentration above minimal inhibitory concentration). This pharmacokinetic/pharmacodynamic (PK/PD) target is associated with better bacterial eradication and therapeutic outcome⁸. Some authors suggest that maximum killing of bacteria occurs when serum concentrations are maintained above the MIC of the causative pathogen for four to five times the MIC ($fT > 4-5 \times MIC$)⁹⁻¹². Susceptibility data for confirmed or suspected pathogens are used to establish the MIC target. Where local data are not available or β -lactam antibiotic was introduced on empirical ground, the highest MIC in the susceptible range is selected from breakpoints published by the European Committee on Antimicrobial Susceptibility Testing (EUCAST)¹³. Effective antibiotic concentrations need to be achieved in the interstitial fluid of tissues as this is the site of most infections⁵. For infections in which tissue penetration is crucial, it is necessary to ensure an adequate β -lactam antibiotic concentration at the site of infection^{14,15}. Severe infections can cause vascular dysfunction including microvascular failure, which can impair ATB delivery into body tissues. Furthermore, infections in the ICU are often caused by pathogens with higher MICs compared with other clinical settings¹⁶. Thus, higher serum ATB concentrations might be required in intensive care patients to increase the likelihood of effective antibiotic concentrations at the site of infection.

In this respect, therapeutic drug monitoring (TDM) of β -lactam antibiotics has a crucial role in optimising adequate antibiotic concentrations in critically ill patients. TDM of some β -lactam antibiotics has already been implemented in certain laboratories in the Czech Republic. In our hospital, TDM of five β -lactam antibiotics (meropenem, ceftazidime, cefotaxime, cefepime and piperacillin/tazobactam) has been available routinely from January 2019, with meropenem being one of the most commonly measured β -lactam ATB. Meropenem is a carbapenem ATB characterized by a broad antibacterial spectrum used for the treatment of serious infecti-

ons including hospital-acquired infections (e.g. sepsis, severe pneumonia, complicated intra-abdominal infections). Meropenem is a hydrophilic ATB with very low plasma protein binding (approximately 2%) and it achieves good penetration into a wide range of tissues. Meropenem undergoes primarily renal elimination, extra-renal elimination accounts for 20% up to 50% in conditions of reduced renal function^{17,18}. A large inter-patient variability in meropenem concentrations after standard dosing has been described in critically ill patients^{19,20}. Meropenem has been shown to be readily dialyzable and effectively removed by haemodialysis¹⁸. A strong relationship between renal function and meropenem exposure and consequently PK/PD target attainment has been observed²⁰. The main objective of this retrospective study was to determine whether the currently used meropenem dosages in our hospital provide adequate serum concentrations and utility of β -lactam TDM in routine clinical practice.

Experimental part

Patient selection

This is a retrospective study performed at the University Hospital Ostrava. TDM of meropenem has been available routinely from January 2019. All patients admitted to any of our intensive care unit between January 2019 and July 2020 were considered for inclusion. Exclusion criteria were: age less than 18 years and admission to another than intensive care unit. Meropenem dosing was at the discretion of the treating physician. Demographic data, including age, sex, height, renal function and presence of renal replacement therapy were collected.

Blood sampling

Blood samples taken during the first meropenem concentration monitoring were included. Only trough serum meropenem concentrations were taken. Meropenem dosing data including the dose, infusion duration, frequency of administration, the time of dosing and sampling, and the day of meropenem therapy were collected. The TDM service is provided in our hospital on daily basis during week days, results are typically available within the next antibiotic dose. Antibiotic dosing is optimised using an iterative process of TDM combined with Bayesian forecasting within dosing software (MWPharm 3.30).

Meropenem serum concentration analysis

Blood samples were processed and stored according to validation protocol to maintain integrity. Total serum meropenem concentrations were determined by liquid chromatography-tandem mass spectrometry method. The sample preparation procedure included precipitation of protein with a mixture composed of methanol : acetonitrile (3 : 2, v/v). The method was validated by the US Food and Drug Administration (FDA) rules as follows: Linearity was found between 1–200 mg/L. The within-day and between-day precision and accuracy were measured at three concentration levels. Coefficients of varia-

tion of all tested concentrations were between 1.6–14.9% and recovery 93.1–109.5%, respectively. The method was tested by external quality assurance based on proficiency testing schemes (external quality control EQC Instand Germany) twice a year.

PK/PD data

In most of the patients meropenem was initiated empirically. Therefore, for the evaluation of achievement of PK/PD targets, MIC of the pathogens defined by the EUCAST was selected. The highest MIC for susceptible bacteria to meropenem was chosen: clinical breakpoint for susceptibility MIC 2.0 mg/L, clinical breakpoint for intermediate pathogens MIC 8.0 mg/L. Attainment of PK/PD target 100% T > MIC and 100% T > 5 × MIC was evaluated. The consensus about the upper limit of β-lactam antibiotics serum concentrations has not been reached yet. Some authors arbitrarily selected the PK/PD 100% T > 10 × MIC as an upper limit for β-lactam antibiotics dose reduction, exposure above this PK/PD target is likely of no additional therapeutic value, but there may be an increased risk of toxicity^{11, 21}.

Data and statistical analysis

Continuous data are presented as median with interquartile range, categorical data are reported as numbers and percentages. Achievement of various PK/PD targets between groups of patients with and without renal replacement therapy was compared by the Fisher's exact test. A value of P < 0.05 was considered statistically significant. Statistical analysis was performed using the GraphPad Prism for Windows version 5.0 (GraphPad Prism Software, Inc).

Results

Patient characteristics

Eighty three intensive care patients were enrolled in this study. For demographic and clinical characteristics see Table 1. Patients were divided into three groups according to their renal function and presence of renal re-

placement therapy:

1. non-RRT patients (patients not on any renal replacement therapy),
2. patients on intermittent dialysis either chronic or acute (iHD),
3. patients on continuous renal replacement therapy (CRRT).

Meropenem was mostly used for the treatment of sepsis, the most common source of infection were the lungs (30.7%), followed by the urinary tract (14.9%), gastrointestinal tract (10%), skin and soft tissue (5.8%) and in 10% the source of infection was not specified.

PK/PD data

The data describing the meropenem dose, meropenem serum trough concentrations and the achievement of PK/PD targets are depicted in Table 2. A large variability in meropenem trough serum concentrations was observed in each patient group. Even when only meropenem serum concentrations at the same daily dose (6 g daily, which was the most common administered dose) were chosen, the variability was still considerable.

When aiming at the lowest PK/PD target for susceptible pathogens (100% T > MIC, MIC = 2.0 mg/L), 100% of patients on iHD and CRRT achieved this target, in patients without any renal replacement therapy the achievement of the target was a little bit lower. For pathogens with intermediate susceptibility, 100% T > MIC for the highest MIC in this range (MIC 8.0 mg/L) was attained in all patients on CRRT and slightly less in patients on iHD. In the group of patients without any renal replacement therapy, 74% of patients achieved this PK/PD target. Patients on renal replacement therapy were more likely to achieve the highest PK/PD target 100% T > 5 × MIC for both MIC values (MIC 2.0 mg/L and 8.0 mg/L), P < 0.05. Higher proportion of patients on RRT would also require meropenem dose reduction if upper limit 100% T > 10 × MIC (MIC 2.0 mg/L) was chosen, P < 0.05.

Discussion

Critically ill patients exhibit extreme inter-individual variability in pharmacokinetic parameters, making decision about the right antibiotic dose difficult. Traditionally, TDM of antibiotics has been employed to minimise toxicity of glycopeptides and aminoglycosides. However, with an increasing number of less sensitive pathogens, large pharmacokinetic variability and increasing intensive care possibilities, TDM concern of these antibiotics has also spread to ensure adequate therapeutic concentrations. With improving understanding of altered pharmacokinetics in critically ill patients, the TDM of antibiotics has also expanded to β -lactams^{11, 21}. Insufficient β -lactam concentrations have been observed in the early phase of severe sepsis and septic shock under standard antibiotic doses²². TDM of β -lactam antibiotics has been available in our hospital from early 2019. The results of our study retrospectively describe meropenem serum concentrations taken at first TDM sampling in our intensive care patients. Several studies have addressed

meropenem pharmacokinetics in ICU septic patients, a large heterogeneity of PK parameters was found^{19, 23, 24}. In accordance with those findings we observed a large variability in meropenem trough serum concentrations in our intensive care patients, even for the same daily dose. Higher proportion of patients on renal replacement therapy (intermittent or continuous) achieved the PK/PD target compared to patients without renal replacement therapy. Roberts JA et al. evaluated practicality and utility of β -lactam TDM in their prospective study in critical care unit. According to TDM meropenem dose adjustment was required in 84% of patients with 57% of patients requiring dose increases and 27% of patients requiring dose decreased after the first TDM. A PK/PD target of 100% $fT > 4-5 \times MIC$ and 100% $fT < 10 \times MIC$ was arbitrarily chosen to maximise the likelihood of clinical cure and minimize the toxicity¹¹. When choosing the same PK/PD targets, dose adjustment would be required in 81.9% of our patients for MIC 2.0 mg/L, a finding similar to a previous study. However, only 18.1% of patients would require dose increases and on the contrary

up to 63.9% of patients would require dose decreases. In a fear of under-dosing and to maximize meropenem exposure, most of our patients received the maximal recommended meropenem dose 6 g daily, without any dose adjustment according to renal functions compared to 3 g daily in normal renal function in the previous study. When adjusting meropenem PK/PD target for MIC 8.0 mg/L, dose adjustment would be required in 67.4% of patients (of them 57.8% of patients requiring dose increases and 9.6% dose decreases). However, there is still unclarity regarding the best PK/PD target for β -lactam antibiotics TDM^{11, 25, 26}. Even, when the PK/PD target was set at $ft > 50\%$ MIC, 16% of intensive care patients did not achieve this most conservative target and these patients were 32% less likely to have a positive clinical outcome²⁵. Critically ill patients have larger volume of distribution, varying renal functions (either decreased or augmented), have low albumin concentrations and may require some artificial organ support²⁷. However, dosing regimens for antibiotics are generally based on studies in healthy volunteers or patients not critically ill. Application of these regimens to critically ill patient may lead to sub-therapeutic concentrations and clinical failure^{28–30}. A great deal of work has been published on the pharmacokinetics of β -lactam antibiotics in intensive care patients^{23, 24, 31, 32}. However, due to great inter-individual variability as a result of multiple variables, extrapolation of these data cannot be applicable to every patient. Thus implementation of TDM of β -lactam antibiotics in routine clinical practice seems crucial for individualization of the optimal dose in a critical care patient.

β -lactam antibiotics exert its efficacy mostly in tissues. Although it has been commonly believed that most antibiotics nearly achieve equilibrium in tissues and plasma, recent studies have indicated that the antibiotic distribution process is characterized by high intertissue and intersubject variabilities and that target site drug levels may substantially differ from corresponding plasma drug levels. Suboptimal target site concentrations may have important clinical implications, as they may explain therapeutic failure and may also trigger bacterial resistance^{14, 23, 33}. However, measurement of β -lactam concentrations at the site of infection is not performed routinely and is reserved mainly for clinical studies. Choosing the “aggressive” PK/PD target ($T > 4–5 \times \text{MIC}$) one might reduce the risk of tissue underexposure. Prolonged or continuous infusions of β -lactams have consistently been shown to improve PK/PD target attainment, particularly in patients with severe infections given the increasing resistance rate^{34, 35}. Some studies have suggested a clinical benefit of prolonged/continuous infusions versus intermittent bolus administrations^{35–38}. On the other hand, high β -lactam concentrations may lead to a higher risk of toxicity, especially neurotoxicity. The most vulnerable group of patients are those with renal dysfunction. However, the toxic concentration threshold is yet unknown. The PK/PD 100% $T > 8–10 \times \text{MIC}$ as an upper limit for β -lactam antibiotics dose reduction has been chosen arbitrarily by some authors^{11, 21, 26}. Some studies have fo-

cused on the concentration–neurotoxicity relationship of β -lactams in ICU patients with the aim to define thresholds above which toxicity is more likely^{39, 40}.

There are limitations of our study. First, this is a retrospective observation of meropenem serum concentrations at the first TDM occasion, this study was not designed to evaluate clinical outcome of the patients or concentration-related toxicity. Second, blood samples were taken at the discretion of treating physician, meropenem serum concentrations in some patients might not be in the steady-state. Third, PK/PD targets were based on the highest MIC in the susceptibility range from EUCAST, which might be higher than those of isolated pathogens. However, in most of the patients, meropenem was initiated empirically, with further de-escalation according to cultivations. Using these highest MIC values we elected the PK/PD target that would maximise meropenem exposure in intensive care patients given the non-standard pharmacokinetics and occurrence of less sensitive pathogens in these patients. Fourth, only total serum meropenem concentrations were analysed. By measuring the unbound concentrations it is more likely to have similar concentrations to those present at the site of infection. However, meropenem binding to serum albumin is negligible (about 2%), so we do not assume a significant difference between total and unbound meropenem serum concentration¹⁷.

Conclusion

In conclusion, we have observed that meropenem trough serum concentrations vary widely in critically ill patients using the same dose. Administration of a standard β -lactam antibiotic dose to a critically ill patient may not lead to adequate exposure. Thus, a personalised dosing regimen is crucial for achievement of beneficial clinical outcome. Implementation of TDM of β -lactams in routine clinical practice is a useful tool to optimise β -lactam dosing in critically ill patients. Ideally, TDM of β -lactams should be performed within the first 2–3 days after antibiotic initiation, so that early dose adjustment could be performed to ensure rapid achievement of adequate antibiotic exposure. As intraindividual β -lactam concentration may vary over time in critically ill patients, repeated therapeutic drug monitoring may be required until the patient is stable.

Conflict of interest: none.
